Debrief: read after you open the envelope

1. Your score

Weighted service-hours lost is your headline score:

> for every end-use facility, hours out × its weight, all added up.

Unweighted hours out sits beside it: the same hours with every facility counted the same.

Lower is better on both. The two can rank outcomes differently. Ten hours without a cell mast (weight 1) and ten hours without the main hospital (weight 10) count the same in unweighted hours. On the weighted score the hospital costs ten times as much. The weights decide what counts as the worst outcome, and choosing them is a judgment about what a community needs most. The game uses the Lifeline weights, which put life-safety services first.

2. Compare, line by line

Lay your sheets beside the envelope's:
1. Crew sheet against the engine's timeline. Same jobs, same order, same times?
2. Event log. Find the first event where you and the engine differ. Everything after it may follow from that one difference, so fix the first and re-check the rest.
3. Outage sheet. Facility by facility: same facilities out, same hours?
4. Every difference gets a cause, written on the feedback sheet:
- a slip: an arithmetic or reading error; the pack was clear;
- an unclear pack: a rule card or node card could fairly be read your way. Your decision log should show it;
- the model: you followed the cards exactly and the engine did something else. This is the most valuable finding of all, because it means the model needs a second look.

3. Why this matters

You just did what a planner must do after a storm: follow damage through dependencies to see who loses service, for how long, and what the crews can do about it. You did it knowing everything: every dependency, every back-up, every rule.

A real planner doesn't know everything. Public sources show where the facilities are, but rarely who depends on whom. So a planner often works from a flattened picture: the facilities, with the connections between networks guessed or left out. The research behind this game asks how much that costs: how much worse are the decisions made from a flattened picture than from one that carries the dependencies? It does so on worlds like this island, where the true answer is known.

Your trace, compared with the engine's, is the first check of that machinery: a person, working from the cards alone, should reach the same answer the computer does. Where you don't, you've found something we need to know.
